# Divide and Conquer Algorithms

Last Updated: August 30th, 2025

## Introduction

A divide-and-conquer algorithm A follows the following general steps.

Base Case If the problem instance is O(1) in size, then use a brute-force procedure that requires O(1) steps.

**Divide** Divide the problem instance into one or more subproblem instances, each having a size that is smaller than the original instance.

Conquer Each subproblem instance is solved by making a recursive call to A.

Combine Combine the subproblem-instance solutions into a final solution to the original problem instance.

The following are some problems that can be solved using a divide-and-conquer algorithm.

Binary Search locating an integer in a sorted array of integers

- Quicksort and Mergesort sorting an array of integers
- Order Statistics finding the k th least or greatest integer of an array

Convex Hulls finding the convex hull of a set of points in  $\mathbb{R}^n$ 

Minimum Distance Pair finding two points from a set of points in  $\mathbb{R}^2$  that are closest

- Matrix Operations matrix inversion, matrix multiplication, finding the largest submatrix of 1's in a Boolean matrix.
- Fast Fourier Transform finding the product of two polynomials
- Maximum Subsequence Sum finding the maximum sum of any subsequence in a sequence of integers.
- Minimum Positive Subsequence Sum finding the minimum positive sum of any subsequence in a sequence of integers.
  - Multiplication of Binary Numbers finding the product of two binary numbers

From an analysis-of-algorithms perspective, some divide-and-conquer algorithms have interesting proofs of correctness, while bounding the number of required steps may seem more interesting for others. In the latter case this involves determining the big-O growth of a function T(n) that satisfies a divide-and-conquer recurrence. Hence, the techniques from the Recurrences lecture prove quite useful. Some algorithms require a degree of mathematical proof, but the proofs usually seem more palpable than those required for, say, greedy algorithms. Quite often the correctness of the algorithm seems clear from its description. As for implementation, most divide-and-conquer algorithms act on arrays of numbers, matrices, or points in space, and usually do not require special data structures for their implementation.

# 1 Hoare's Quicksort

**Definition 1.1.** The **median** of an array a of n numbers, denoted median(a), is defined as follows.

**Odd** n a number  $x \in a$  for which (n-1)/2 members of a are less than or equal to x and (n-1)/2 members of a are greater than or equal to x

**Even** n two numbers  $x, y \in a$  for which for which (n-2)/2 members of a are less than or equal to x and (n-2)/2 members of a are greater than or equal to x

Thus, when n is odd median(a) = x, while  $median(a) = \{x, y\}$  when n is even.

 $\alpha_1 = \gamma_2$   $\alpha_2 = \gamma_2$ 

6

**Example 1.2.** Determine the median of 7, 5, 7, 3, 4, 8, 2, 3, 7, 8, 2, and the medians of 4, 5, 10, 12, 6, 3.

Solution. Median  $(a_1) = 5$  median  $(a_2) = \{5,6\}$ 

Quicksort is considered in practice to be the most efficient sorting algorithm for arrays of data stored in local memory. Quicksort is similar to Mergesort in that the first (non base case) step is

to divide the input array a into two arrays  $a_{\text{left}}$  and  $a_{\text{right}}$ . However, where as Mergesort simply divides a into two equal halves, Quicksort performs the **Partitioning Algorithm** on a which is described below.

#### 1.1 Partitioning Algorithm

Calculate Pivot The pivot M is an element of a which is used to divide a into two subarrays  $a_{\text{left}}$  and  $a_{\text{right}}$ . Namely, all elements  $x \in a_{\text{left}}$  satisfy  $x \leq M$ , while all elements  $x \in a_{\text{right}}$  satisfy  $x \geq M$ . A common heuristic for computing M is called **median-of-three**, where M is chosen as the median of the first, last, and middle elements of a; i.e. median(a[0], a[(n-1)/2], a[n-1]).

**Swap Pivot** Swap the pivot with the last member of a located at index n-1 (M is now in a safe place).

**Initialize Markers** Initialize a left marker to point to a[0]. Initialize a right marker to point to a[n-2]. Let i=0 denote the current index location of the left marker, and j=n-2 denote the current index location of the right marker.

#### **Examine Markers** Do one of the following

- If  $i \geq j$ , then swap a[i] with M = a[n-1]. In this case  $a_{\text{left}}$  consists of the first i elements of a, while  $a_{\text{right}}$  consists of the last n-i-1 elements of a. Thus, a[i] = M is to the right of  $a_{\text{left}}$  and to the left of  $a_{\text{right}}$ .
- Else if  $a[i] \ge M$  and  $a[j] \le M$ , then swap a[i] with a[j], increment i, and decrement j.
- Else if a[i] < M, then increment i.
- Else decrement j. //must have a[j] > M

#### While i < j.

Once the Partitioning algorithm has partitioned a into  $a_{left}$  and  $a_{right}$ , then Quicksort is recursively called on both the left and right arrays, and the algorithm is complete.

Notice how Quicksort and Mergesort differ, in that Mergesort performs O(1) steps in partitioning a, but O(n) steps to combine the sorted subarrays, while Quicksort performs O(n) steps to partition a, and requires no work to combine the sorted arrays. Moreover, Quicksort has the advantage of sorting "in place", meaning that no additional memory is required outside of the input array. Indeed, the Partitioning algorithm only requires swapping elements in the original array, and, the sorting of each subarray only uses that part of a where the elements of the subarray are located. For example, if  $a_{\text{left}}$  occupies locations 0 through 10 of a, then only those locations will be affected when Quicksort is called on input  $a_{\text{left}}$ . It is this in-place property that gives Quicksort an advantage over Mergesort.

**Example 1.3.** Demonstrate the quicksort algorithm using the array 5, 8, 6, 2, 7, 1, 0, 9, 3, 4, 6.

Running time of Quicksort. The running time (i.e. number of steps T(n) for an array size of n comparables) of quicksort depends on how the pivot is chosen. Later in this lecture we demonstrate how to find an exact median in O(n) steps. This algorithm could in theory be applied to finding the Quicksort pivot. Using this approach quicksort has a running time of  $O(n \log n)$ , since  $O(n \log n)$  satisfies the recurrence

$$T(n) = 2T(n/2) + n.$$

However, in practice the pivot is chosen at random, or by using a heuristic such as median-of-three. Although both options offer a worst case running time of  $O(n^2)$ , in practice they outperform the approach that computes the median as the pivot. The worst case is  $O(n^2)$  because, e.g., either approach could result in a sequence of pivots for which  $a_{\text{left}}$  always has a length equal to one. In this case the lengths of each  $a_{\text{right}}$  subarray are respectively,  $n-2, n-4, n-6, \ldots$  down to either 1 or 2. And since the Partition algorithm must be performed on each of these arrays, it yields a total running time of (assuming n is odd)

$$T(n) = \underbrace{O(n + (n-2) + (n-4) + \dots + 1)}_{(n-2) + (n-4) + \dots + 1)} = O(\sum_{i=1}^{(n+1)/2} (2i-1)) = O(n^2),$$
and so Quicksort has a worst-case quadratic running time.
$$(n+1)/2$$

### 2 Finding Order Statistics

The k th **order statistic** of an array a of n elements is the k th least element in the array,  $k = 0, \ldots, n-1$ . Moreover, finding the k th order statistic of a can be accomplished by sorting a and returning the k th element in the sorted array. Using Mergesort, this will take  $\Theta(n \log n)$  steps. We now describe an algorithm that is similar to Quicksort and reduces the running time for finding the k th statistic down to O(n) steps.

For the moment assume that we have access to an **oracle** that can provide the median of an array a at a computational cost of one step. Also, assume that, in addition to a and k, our algorithm has two additional inputs, **lower** and **upper**, that respectively give lower and upper bounds on the index of a where the k th statistic is located. Thus, our algorithm/function has the following signature (here we assume an array of integers).

```
int find_statistic(int a[], int k, int lower, int upper)
```

For example, if a has a length of n, then the initial call would be

```
find_statistic(a,k,0,n-1)
```

```
//Returns the kth statistic of a which is located at an index
//i for which i >= lower and i <= upper</pre>
int find_statistic(int a[], int k, int lower, int upper)
{
    //Assume base case of 5 or fewer elements
    if(upper-lower <= 4)</pre>
        return find_statistic_base_case(a,k,lower,upper)
    //The oracle returns the index of where a's median is located
    int index = oracle(a,lower,upper)
    int M = a[index]
    //partition_algorithm returns the index of the final pivot location
    index = partition_algorithm(a,lower,upper,index)
    if(k == index)//kth least element equals the pivot
     return M
    if(k < index)</pre>
        return find_statistic(a,k,lower,index-1)
    //Must have k > index
    return find_statistic(a,k,index+1,upper)
}
```

Letting T(n) denote the running time of find\_statistic, we see that T(n) satisfies

$$T(n) \le T(n/2) + n.$$

Indeed, the oracle call counts for one step, the Partition algorithm counts for n steps (assuming n = upper - lower + 1), and the recursive call (assuming  $k \neq \text{index}$ ) contributes another T(n/2) steps. Thus, by Case 3 of the Master theorem, we see that T(n) = O(n).

Now all that remains is to replace the oracle function. As a first attempt, since the k = n/2 statistic is a median of a, we could replace the function call

oracle(a,lower,upper)

with

*11* 

find\_statistic(a,n/2,lower,upper)

The problem here is that the input to this recursive call does not represent a *smaller subproblem*. In other words, if n = upper - lower + 1 is the size of the original problem, then n is also the size of the subproblem, since neither has the lower value been increased, nor has the upper value been decreased. As a result, if n > 5, then the base case will never be attained, and the function's execution will result in an infinite loop.

Thus, when computing the median, we must reduce the problem size by finding the median of only some of the elements of a, and yet hope that the answer still provides for a good enough partition. To this end, the elements that will be used are determined as follows. Divide a into  $\lceil n/5 \rceil$  groups of five elements (the last group may contain fewer than five). Calculate the median of each group, and place it in the array  $a_{\text{medians}}$ . This array has a length of  $\lceil n/5 \rceil$  elements. Now replace the function call

oracle(a,lower,upper)

with

$$\texttt{find\_statistic}(a_{\mbox{medians}}, \frac{1}{2} \lceil n/5 \rceil, 0, \lceil n/5 \rceil - 1).$$

In other words, the new pivot is equal to the median of the medians of each group of five.

**Theorem 1.** The find\_statistic algorithm has a worst-case running time of T(n) = O(n).

Proof of Theorem 1. T(n) satisfies the recurrence call to find S and  $T(n) \leq T(n/5) + T(bn) + n$ , for  $T(n) \leq T(n/5) + T(bn) + n$ , we diam S

where T(n/5) is the cost of finding the median of  $a_{\text{medians}}$ , n is the cost of the Partitioning algorithm, and T(bn) is the cost of the final recursive call (if necessary). Here, b is a fraction for which  $\lfloor bn \rfloor$ represents the worst-case length of either  $a_{\text{left}}$  or  $a_{\text{right}}$ . Using the oracle, we had b = 1/2, since the oracle returned the exact median of a which was used as the partitioning pivot. But now the pivot is determined by the median of  $a_{\mathrm{medians}}$ .

Claim. The median M of  $a_{\text{medians}}$  is greater than or equal to (respectively, less than or equal to)

elements of a, assuming  $n \ge 180$ .

Proof of Claim. Since M is the modified form

**Proof of Claim.** Since M is the median of  $a_{\text{medians}}$  it must be greater than or equal to at least  $L = \lfloor \frac{1}{2} \lceil \frac{n}{5} \rceil \rfloor$  elements of  $a_{\text{medians}}$ . Moreover, we subtract 2 from L to account for the median M itself, and also the median of the last group, which might not have five elements. Thus, L-2 is the number of elements of  $a_{medians}$  that are distinct from M, and come from a group that has five elements, and which are less than or equal to M. But, since each of these elements is the median of its group, there must be two additional elements in its group that are also less than or equal to M. Hence, there are 3 elements in the group that are less than or equal to M, giving a total of

$$3(L-2) = 3(\lfloor \frac{1}{2} \lceil \frac{n}{5} \rceil \rfloor - 2)$$

elements of a that are less than or equal to M.

Furthermore, using the inequalities,  $\lfloor x \rfloor \geq x-1$  and  $\lceil x \rceil \geq x$ , we arrive at  $3(L-2) \geq \frac{3n}{10}-9$ . Finally, basic algebra shows that the inequality

$$\frac{3n}{10} - 9 \ge n/4$$

is true provided  $n \geq 180$ . A symmetrical argument may be given for establishing that M is also less than or equal to at least n/4 elements of a.

To finish the proof of Theorem 1, since there are at least n/4 elements to the left and right of M, we know that both  $a_{\text{left}}$  and  $a_{\text{right}}$  cannot have lengths that exceed n - n/4 = 3n/4. Thus, b = 3/4, and we have

$$T(n) \le T(n/5) + T(3n/4) + n.$$

Finally, by Exercise 16 from the Recurrence Relations lecture with a = 1/5 and b = 3/4, we have  $a + b = 1/5 + 3/4 = 19/20 \le 1$  which implies that T(n) = O(n).

 $T(n) = T(\alpha n) + T(bn) + n$  and  $\alpha + b < 1$ Then T(n) = O(n)

### 3 Strassen's Algorithm for Matrix Multiplication

Given two  $n \times n$  matrices A and B, the standard way to compute their product C = AB is to compute entry  $c_{ij}$  of C by taking the dot product of row i of A with column j of B. Furthermore, since a dot product requires  $\Theta(n)$  operations and there are  $n^2$  entries to compute, we see that the standard approach requires  $\Theta(n^3)$  steps.

One interesting property of matrices is that their entries do not necessarily have to be real numbers. They can be any kind of element for which addition, subtraction, and multiplication have been defined. Therefore, the entries of a matrix can be matrices! For example, below is a  $2 \times 2$  matrix whose entries are themselves  $2 \times 2$  matrices.

$$\left(\begin{array}{ccc}
\left(\begin{array}{ccc}
2 & -1 \\
4 & -2
\end{array}\right) & \left(\begin{array}{ccc}
-1 & 3 \\
5 & 0
\end{array}\right) \\
\left(\begin{array}{ccc}
4 & 1 \\
-3 & 0
\end{array}\right) & \left(\begin{array}{ccc}
2 & 6 \\
-2 & 3
\end{array}\right)
\right)$$

**Theorem 3.1.** Let A and B be two square  $n \times n$  matrices, where n is even. Let  $A_{11}$ ,  $A_{12}$ ,  $A_{21}$ , and  $A_{22}$  represent the four  $\frac{n}{2} \times \frac{n}{2}$  submatrices of A that correspond to its four **quadrants**. For example,  $A_{11}$  consists of rows 1 through n/2 of A whose entries are restricted to columns 1 through n/2. Similarly,  $A_{12}$  consists of rows 1 through n/2 of A whose entries are restricted to columns n/2 + 1 through n/2. Finally,  $A_{21}$  and  $A_{22}$  represent the bottom half of A. Thus, A can be written as

$$A = \left(\begin{array}{cc} A_{11} & A_{12} \\ A_{21} & A_{22} \end{array}\right)$$

Submatrices  $B_{11}$ ,  $B_{12}$ ,  $B_{21}$ , and  $B_{22}$  are defined similarly. Finally, let  $\hat{A}$  and  $\hat{B}$  be the  $2 \times 2$  matrices whose entries are the four quadrants of A and B respectively. Then the entries of  $\hat{C} = \hat{A}\hat{B}$  are the four quadrants of C = AB.

**Proof.** Consider the (i, j) entry of C = AB. For simplicity of notation, assume that (i, j) lies in the upper left quadrant of C. Then we have

$$c_{ij} = \sum_{k=1}^{n} a_{ik} b_{kj}.$$

We must show that  $c_{ij}$  is equal to entry (i, j) of  $\hat{c}_{11}$ , where  $\hat{c}_{11}$  is the  $\frac{n}{2} \times \frac{n}{2}$  matrix that is entry (1, 1) of  $\hat{C}$ . To simplify the indexing notation, let

$$\hat{A} = \begin{pmatrix} p & q \\ r & s \end{pmatrix}$$
 and  $\hat{B} = \begin{pmatrix} t & u \\ v & w \end{pmatrix}$ 

be the respective quadrant matrices of A and B. Then matrices p through w are all  $\frac{n}{2} \times \frac{n}{2}$  matrices. Now,

$$\hat{c}_{11} = A_{11}B_{11} + A_{12}B_{21} = pt + qv$$

is the sum of two matrix products. Thus, the (i, j) entry of  $\hat{c}_{11}$  is equal to

$$\sum_{k=1}^{n/2} p_{ik} t_{kj} + \sum_{k=1}^{n/2} q_{ik} v_{kj} =$$

$$\sum_{k=1}^{n/2} a_{ik} b_{kj} + \sum_{k=1}^{n/2} a_{i(k+n/2)} b_{(k+n/2)j} =$$

$$\sum_{k=1}^{n/2} a_{ik} b_{kj} + \sum_{k=n/2}^{n} a_{ik} b_{kj} =$$

$$\sum_{k=1}^{n} a_{ik} b_{kj} = c_{ij},$$

and the proof is complete.

Example 3.2. Given the matrices

$$\overrightarrow{A} = 
\begin{bmatrix}
-2 & -4 & 1 & 0 \\
4 & -2 & -3 & 1 \\
1 & 0 & -4 & -2 \\
-3 & 2 & 1 & -4
\end{bmatrix}$$

$$B = 
\begin{bmatrix}
-1 & \cancel{4} & -1 & 2 \\
3 & -3 & \cancel{4} & -1 \\
-1 & 2 & -2 & -1 \\
-2 & -2 & -1 & 4
\end{bmatrix}$$

Verify that quadrant  $C_{11}$  of C = AB is equal to entry (1, 1) of  $\hat{C} = \hat{A}\hat{B}$ .

Solution. We have  $C_{11} = \begin{pmatrix} -11 & 6 & -16 & -1 \\ -9 & 14 & -7 & 17 \\ 7 & 0 & 9 & -2 \\ 16 & -8 & 13 & -25 \end{pmatrix}.$ Moreover,  $A_{11}B_{11} + A_{12}B_{21} = \begin{pmatrix} -2 & -4 \\ 4 & -2 \end{pmatrix} \begin{pmatrix} -1 & 4 \\ 3 & -3 \end{pmatrix} + \begin{pmatrix} 1 & 0 \\ -3 & 1 \end{pmatrix} \begin{pmatrix} -1 & 2 \\ -2 & -2 \end{pmatrix} = \begin{pmatrix} -10 & 4 \\ -10 & 22 \end{pmatrix} + \begin{pmatrix} -1 & 2 \\ 1 & -8 \end{pmatrix} = \begin{pmatrix} -11 & 6 \\ -9 & 14 \end{pmatrix} = C_{11}.$ 

We leave it as an exercise to verify the other three equations:

$$A_{11}B_{12} + A_{12}B_{22} = C_{12},$$

$$A_{21}B_{11} + A_{22}B_{21} = C_{21},$$

and

$$A_{21}B_{12} + A_{22}B_{22} = C_{22}.$$

Theorem 2 leads to the following divide-and-conquer algorithm for multiplying two  $n \times n$  matrices A and B, where n is a power of two. Let

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \text{ and } B = \begin{pmatrix} e & f \\ g & h \end{pmatrix}$$

be two  $n \times n$  matrices, where n is a power of two, and, e.g. a represents the  $n/2 \times n/2$  upper left quadrant of A, b the  $n/2 \times n/2$  upper right quadrant of A, etc.. The goal is to compute C = AB, where

$$C = \left(\begin{array}{cc} r & s \\ t & u \end{array}\right).$$

The algorithm divides A and B into their four quadrants and proceeds to make 8 recursive calls to obtain the  $n/2 \times n/2$  products ae, bg, af, bh, ce, dg, cf, and dh. Finally, these products are added to obtain

$$\begin{aligned}
r &= ae + bg, \\
s &= af + bh, \\
t &= ce + dg, \\
u &= cf + dh.
\end{aligned}$$

Letting T(n) denote the running time of the algorithm, then T(n) satisfies

where the first term is due to the 8 recursive calls on matrices whose dimensions are n/2, and the second term  $n^2$  represents the big-O number of steps needed to divide A and B into their quadrants, and to add the eight products that form the quadrants of C. Therefore, by Case 1 of the Master Theorem,  $T(n) = \Theta(n^3)$ , and the algorithm's running time is equivalent to the running time when using the standard matrix-multiplication procedure.

#### 3.1 Strassen's improvement

Strassen's insight was to *first* take linear combinations of the quadrants of A and B, and then multiply these combinations. By doing this, he demonstrated that only 7 products are needed. These products are then added to obtain the quadrants of C. Moreover, since computing a linear combination of A and B quadrants takes  $\Theta(n^2)$  steps (since we are just adding and subtracting a constant number of  $n/2 \times n/2$  matrices), the recurrence produced by Strassen is

$$T(n) = 7T(n/2) + n^2,$$

which improves the running time to  $n^{\log 7}$ , where  $\log 7 \approx 2.8$ .

#### Strassen's Seven Matrix Products

1. 
$$A_1 = a$$
,  $B_1 = f - h$ ,  $P_1 = A_1B_1 = a(f - h) = af - ah$ 

2. 
$$A_2 = a + b$$
,  $B_2 = h$ ,  $P_2 = A_2B_2 = (a + b)h = ah + bh$ 

3. 
$$A_3 = c + d$$
,  $B_3 = e$ ,  $P_3 = A_3B_3 = (c + d)e = ce + de$ 

4. 
$$A_4 = d$$
,  $B_4 = g - e$ ,  $P_4 = A_4 B_4 = d(g - e) = dg - de$ 

5. 
$$A_5 = a + d$$
,  $B_5 = e + h$ ,  $P_5 = A_5B_5 = (a + d)(e + h) = \underbrace{ae + ah + de + dh}$ 

6. 
$$A_6 = b - d$$
,  $B_6 = g + h$ ,  $P_6 = A_6 B_6 = (b - d)(g + h) = bg + bh - dg - dh$ 

7. 
$$A_7 = a - c$$
,  $B_7 = e + f$ ,  $P_7 = A_7 B_7 = (a - c)(e + f) = ae - ce - cf + af$ 

**Example 3.3.** Write r, s, t, u as linear combinations of  $P_1, \ldots, P_7$ .

Solution (verify!).

s linear combinations of 
$$P_1, \dots, P_7$$
.
$$T = ae + bg = P_5 + P_6 - P_2 + P_4$$

$$s = af + bh = P_1 + P_2$$

$$t = ce + dg = P_3 + P_4$$

$$u = cf + dh = -P_7 + P_5 - P_3 + P_1$$

### Divide and Conquer Core Exercises

- 1. Perform the partitioning step of Quicksort on the array 9, 6, 1, 9, 11, 10, 6, 9, 12, 2, 7, where the pivot is chosen using the median-of-three heuristic.
- 2. Perform the partitioning step of Quicksort on the array 6, 2, 7, 6, 7, 10, 10, 1, 9, 8, 4, 3, 5, where the pivot is chosen using the median-of-three heuristic.
- 3. If

$$a = 2, 4, 1, 3, 8, 9, 3, 5, 7, 6, 5, 8, 5$$

serves as input to the Median-of-Five Find Statistic algorithm, then what pivot is used for the algorithm's partitioning step at the root level of recursion?

4. In the Median-of-Five Find Statistic recall that the median M of  $a_{\text{medians}}$  is greater than or equal to (respectively, less than or equal to) at least

$$3(\lfloor \frac{1}{2} \lceil \frac{n}{5} \rceil \rfloor - 2) \ge 3(\frac{1}{2} \cdot \frac{n}{5} - 3) = \frac{3n}{10} - 9 \ge n/4$$

elements of a, assuming  $n \ge 180$ . Re-write the above chain of inequalities if the algorithm used groups of seven rather than groups of five. Provide a new bound for n that must be satisfied in order for the final inequality (i.e.  $\ge n/4$ ) to hold.

5. Use Strassen's algorithm to compute the matrix product

$$\left(\begin{array}{cc} 1 & 3 \\ 7 & 5 \end{array}\right) \left(\begin{array}{cc} 6 & 8 \\ 4 & 2 \end{array}\right)$$

Make sure to compute integer values for  $P_1$  through  $P_7$  and apply them to Strassen's formulas to determine the matrix product.

- 6. Consider Karatsuba's algorithm which we'll call multiply for multiplying two n-bit binary numbers x and y. Let  $x_L$  and  $x_R$  be the leftmost  $\lceil n/2 \rceil$  and rightmost  $\lfloor n/2 \rfloor$  bits of x respectively. Define  $y_L$  and  $y_R$  similarly. Let  $P_1$  be the result of calling multiply on inputs  $x_L$  and  $y_L$ ,  $P_2$  be the result of calling multiply on inputs  $x_R$  and  $y_R$ , and  $P_3$  the result of calling multiply on inputs  $x_L + x_R$  and  $y_L + y_R$ . Then return the value  $P_1 \times 2^{2\lfloor \frac{n}{2} \rfloor} + (P_3 P_1 P_2) \times 2^{\lfloor n/2 \rfloor} + P_2$ . Provide the divide-and-conquer recurrence for this algorithm's running time T(n), and use it to determine the running time. Justify all aspects of your recurrence. Hint: for simplicity you may assume that n is even.
- 7. For the two binary integers x = 11011110 and y = 10111011, determine the top-level values of  $P_1$ ,  $P_2$ , and  $P_3$ , and verify that  $xy = P_1 \times 2^{2\lfloor \frac{n}{2} \rfloor} + (P_3 P_1 P_2) \times 2^{\lfloor n/2 \rfloor} + P_2$ .
- 8. Verify that Karatsuba's algorithm always works by proving in general that  $xy = P_1 \times 2^n + (P_3 P_1 P_2) \times 2^{n/2} + P_2$  for arbitrary x and y. Hint: you may assume that the binary representations of both x and y have even length.
- 9. Given an array a[j] of integers, a subsequence of the array is a sequence of the form  $a[i], a[i+1], a[i+2], \ldots, a[j]$ , where  $i \leq j$ . Moreover, the sum of the subsequence is defined as  $a[i] + a[i+1] + a[i+2] + \cdots + a[j]$ . An instance of the Maximum Subsequence Sum (MSS) problem is an array a of n integers, and the problem is to determine the maximum sum of any of the

subsequences of a. The following divide-and-conquer algorithm may be used to find the MSS. Divide the array a into equal-length subarrays  $a_L$  and  $a_R$ . Let  $\mathrm{MSS}_L$  denote the MSS of  $a_L$ ,  $\mathrm{MSS}_R$  denote the MSS of  $a_R$ . Then calculate  $\mathrm{MSS}_{\mathrm{middle}}$  by adding the MSS of  $a_L$  that ends with the last element of  $a_L$  to the MSS of  $a_R$  that begins with the first element of  $a_R$ . Return the maximum of  $\mathrm{MSS}_L$ ,  $\mathrm{MSS}_R$ , and  $\mathrm{MSS}_{\mathrm{middle}}$ . Provide a divide-and-conquer recurrence relation that describes the running time T(n) of the MSS algorithm and use the Master Theorem to provide its big- $\Theta$  running time. Make sure to defend all aspects of the recurrence.

- 10. For the MSS divide-and-conquer algorithm described in Exercise 9 provide the entire recursion tree for instance a = 4, -3, 2, 1, -4, 5, -3, 2. Label each node with the problem instance that is being solved at that stage of the recursion. Also, next to each node write the MSS its value and (in case the node is interal) indicate if the MSS comes from the left subproblem, right subproblem, or middle of both subproblems.
- 11. An instance of the Minimum Positive Subsequence Sum (MPSS) problem is an array a of nintegers, and the problem is to determine the minimum positive subsequence sum of a (see Exercise 9 for the definition of subsequence sum). The following divide-and-conquer algorithm is similar to the MSS algorithm described in Exercise 9. The only difference is in how to calculate MPSS<sub>middle</sub>. Since both positive and negative sums may be useful for finding a small positive subsequence sum, we must compute all the subsequence sums of  $a_L$  that end with the last element of  $a_L$  and sort them in increasing order and call the resulting array  $b_L$ . Similarly, compute all the subsequence sums of  $a_R$  that begin with the first element of  $a_R$  and sort them in decreasing order and call the resulting array  $b_R$ . Now initialize variable mpss to  $\infty$ . Initialize two index variables i and j to 0. Repeat the following until termination. If  $0 < b_L[i] + b_R[j]$ , then if  $b_L[i] + b_R[j] < \text{mpss}$ , assign mpss the value  $b_L[i] + b_R[j]$ . In either case increment j if possible (or terminate the algorithm in case  $j = |b_R|$ ). Otherwise,  $b_L[i] + b_R[j] \leq 0$  and so we must increment i if possible (or terminate the algorithm in case  $i = |b_L|$ ). Provide a divide-andconquer recurrence relation that describes the running time T(n) of the MPSS algorithm and use the Master Theorem to provide its big- $\Theta$  running time. Make sure to defend all aspects of the recurrence.
- 12. For the MPSS algorithm described in Exercise 11 provide each of the left sums that must be sorted and well as each of the right sums that must be sorted in order to compute  $MPSS_{Middle}$  at the top level of recursion (only!) for the array

$$a = 48, -37, 32, -33, 70, -64, 46, -34, 45, -72, 34, -52.$$

Then compute both  $b_L$  and  $b_R$ . Show each iteration of the algorithm until the algorithm is forced to terminate according to the termination conditions described in the algorithm. Do so by making a table whose columns are  $i, j, b_L[i], b_R[j], b_L[i] + b_R[j]$ , and the current mpss value. Finally, indicate the beginning and ending indices of the subsequence of a that sums to the mpss.

### Solutions to Divide and Conquer Core Exercises

- 1. Pivot = 9.  $a_{\text{left}} = 7, 6, 1, 2, 9, 6, a_{\text{right}} = 11, 12, 9, 10$
- 2.  $a_{\text{left}} = 5, 2, 3, 4, 1, a_{\text{right}} = 10, 7, 9, 8, 6, 7, 10$ , while pivot 6 is permanently placed at index 5.
- 3. The medians of groups  $G_1$ ,  $G_2$ , and  $G_3$  are respectively, 3, 6, and 5. Therefore, the pivot is median(3,6,5) = 5.
- 4. With groups of 7, we replace  $\lceil \frac{n}{5} \rceil$  with  $\lceil \frac{n}{7} \rceil$  since there are  $\lceil \frac{n}{7} \rceil$  groups and hence  $\lceil \frac{n}{7} \rceil$  medians that form the "medians of medians" array whose median serves as the pivot. Also, the leading 3 is replaced by 4 since, e.g., if the pivot is greater than or equal to the median of some group, then it is also greater than or equal to three other members of the group, and we have 1+3=4. Therefore, we have

$$4(\lfloor \frac{1}{2} \lceil \frac{n}{7} \rceil \rfloor - 2) \ge 4(\frac{1}{2} \cdot \frac{n}{7} - 3) = \frac{2n}{7} - 12 \ge n/4$$

so long as  $n \ge (28)(12) = 336$ .

5. We have  $P_1 = 6, P_2 = 8, P_3 = 72, P_4 = -10, P_5 = 48, P_6 = -12, P_7 = -84$  and so

$$r = ae + bg = P_5 + P_6 - P_2 + P_4 = 18$$

$$s = af + bh = P_1 + P_2 = 14$$

$$t = ce + dg = P_3 + P_4 = 62$$

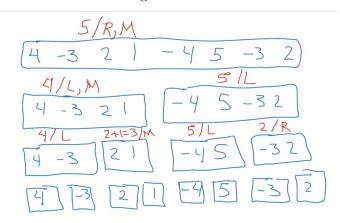

$$u = cf + dh = -P_7 + P_5 - P_3 + P_1 = 66$$

which gives the product matrix

$$\left(\begin{array}{cc} 18 & 14 \\ 62 & 66 \end{array}\right).$$

- 6. T(n) = 3T(n/2) + O(n) yields  $T(n) = \Theta(n^{\log 3})$ . There are three subproblems,  $P_1$ ,  $P_2$ , and  $P_3$  each of size n/2. As for f(n), both  $P_1$  and  $P_2$  can be formed in O(1) steps, while  $P_3$  can be formed with a single O(n) addition. Finally, the output requires four additions/subtractions, each requiring O(n) addition, while multiplying by  $2^{\frac{n}{2}}$  also requires O(n) steps since it requires shifting bits  $\frac{n}{2}$  places to the left.
- 7. x = 111, y = 93,  $x_L = 13$ ,  $x_R = 7$ ,  $y_L = 11$ , and  $y_R = 5$ .  $P_1 = 143$ ,  $P_2 = 35$ ,  $P_3 = 320$ . (64)(143) + (8)(320 143 35) + 35 = 10323 = (111)(93).
- 8. We have  $x = (2^{n/2}x_L + x_R)$  and  $y = (2^{n/2}y_L + y_R)$ . Multiply these together to derive the right side of the equation.
- 9. The running time recurrence satisfies T(n) = 2T(n/2) + O(n). Why? Therefore,  $T(n) = \Theta(n \log n)$ .

10. We have the following recursion tree.

11. The left sums are -64, 6, -27, 5, -32, 16, while  $b_L = -64, -32, -27, 5, 6, 16$ . The right sums are 46, 12, 57, -15, 19, -33, while  $b_R = 57, 46, 19, 12, -15, -33$ .

i	j	$b_L[i]$	$b_R[j]$	$b_L[i] + b_R[j]$	mpss
0	0	-64	57	-12	$\infty$
1	0	-32	57	25	25
1	1	-32	46	14	14
1	2	-32	19	-13	14
2	2	-27	19	-8	14
3	2	5	19	24	14
3	3	5	12	17	14
3	4	5	-15	-10	14
4	4	6	-15	-9	14
5	4	16	-15	1	1
5	5	16	-33	-17	1

Therefore, the mpss equals 1 and represents the sum from a[0] to a[9].

12. The running time recurrence satisfies  $T(n) = 2T(n/2) + O(n \log n)$ . Why?  $T(n) = \Theta(n \log^2 n)$ .

#### **Additional Exercises**

- 1. Provide a permutation of the numbers 1-9 so that, when sorted by Quicksort using median-of-three heuristic, the  $a_{\text{left}}$  subarray always has one element in rounds 1,2, and 3. Note: in general, when using the median-of-three heuristic, Quicksort is susceptible to  $\Theta(n^2)$  worst case performance.
- 2. Given n distinct integers, prove that the greatest element of a can be found using n-1 comparisons, and that one can do no better than n-1.
- 3. Given n distinct integers, show that the second greatest element can be found with  $n+\lceil \log n \rceil -2$  comparisons in the worst case.

- 4. Given n distinct integers, prove the lower bound of  $\lceil 3n/2 \rceil 2$  comparisons in the worst case to determine both the least and greatest element.
- 5. For the Median-of-Five Find Statistic algorithm, does the algorithm still run in linear time if groups of three are used instead of groups of five? Explain and show work.
- 6. Explain how the Median-of-Five Find Statistic Algorithm could be used to modify Hoare's Quicksort so that it requires  $O(n \log n)$  steps in the worst-case.
- 7. The q th quantiles of an n-element array are the q-1 order statistics that divide the sorted array into q equal-sized subarrays (to within 1). In other words, the q th quantiles of an n-element array are the q-1 k th least elements of a, for

$$k = |n/q|, |2n/q|, \dots, |(q-1)n/q|.$$

Provide the 3rd quantiles for the array of integers

- 8. Provide an  $O(n \log q)$ -time algorithm that finds the q th quantiles of an array. Hint: modify the Find-Statistic algorithm so that multiple statistics (i.e. the q th quantiles) can be simultaneously found. At what level of recursion will the algorithm reduce to the original algorithm for just one statistic? Notice that from this level down the algorithm will then run in linear time in the size of the array at that level.
- 9. For the matrices A and B in Example 3.2, compute the remaining quadrants  $C_{12}$ ,  $C_{21}$ , and  $C_{22}$  of C = AB and verify that they are the entries of matrix  $\hat{C} = \hat{A}\hat{B}$ , where, e.g.  $\hat{A}$  is the matrix whose entries are the quadrants of A.
- 10. Prove the other four cases of Theorem 2, i.e. the cases where entry (i, j) of C lies in the upper right, lower left, and lower right quadrant.
- 11. Suppose you want to apply Strassen's algorithm to square matrices whose number of rows are not powers of 2. To do this you, add more columns and rows of zeros to each matrix until the number of rows (and columns) of each matrix reaches a power of 2. The perform the algorithm. If m is the original dimension, and n is the dimension after adding more rows and columns, is the running time still  $\Theta(m^{\log 7})$ ? Explain and show work.
- 12. What is the largest k such that you can multiply  $3 \times 3$  matrices using k multiplications, then you can multiply matrices in time  $o(n^{\log 7})$ ? Explain and show work.
- 13. Professor Jones has discovered a way to multiply 68 × 68 matrices using 132,464 multiplications, and a way to 70 × 70 matrices using 143,640 multiplications. Which method yields the better asymptotic running time? How do these methods compare with Strassen's algorithm?
- 14. Using Strassen's algorithm, describe an efficient way to multiply a  $kn \times n$  matrix with an  $n \times kn$  matrix. You may assume n is a power of 2.
- 15. Show how to multiply the complex numbers a + bi and c + di using only three multiplications of real numbers. The algorithm should take a, b, c, and d as input, and produce the real component ac bd and imaginary component ad + bc. Note that the straightforward approach requires four multiplications. We seek a more clever approach.

- 16. Describe an O(n)-time algorithm that, given an array of n distinct numbers, and a positive integer  $k \leq n$ , determines the k elements in the array that are closest to the median of the array. Hint: first find the median and form a new array that is capable of giving the answer.
- 17. Let a and b be two odd-lengthed n-element arrays already in sorted order. Give an  $O(\log n)$ -time algorithm to find the two medians of all the 2n elements in arrays a and b combined, denoted  $a \cup b$ .

#### Solutions to Additional Exercises

- 1. 173924685 is one possible permutation. Verify!
- 2. Let  $S_0$  denote the set of n integers. While there is more than one integer in  $S_i$ ,  $i \ge 0$ , pair up the integers in  $S_i$ . If  $|S_i|$  is odd, then add the last (unpaired) integer to  $S_{i+1}$ . Perform a comparison on each pair and add the greater integer to  $S_{i+1}$ . Thus, there is a one-to-one correspondence between integers that are left out of the next set  $S_{i+1}$  and comparisons performed (during iteration i). Moreover, since there will be some j for which  $|S_j| = 1$ ,  $S_j$  will contain the greatest integer after a total of n-1 comparisions.
- 3. Since the second greatest integer  $n_2$  does not appear in the final set  $S_j$  (see previous problem), there must exist an iteration i for which  $n_2$  is compared with  $n_1$ , the greatest integer. This is true since  $n_1$  is the only integer that could prevent  $n_2$  from advancing. Thus,  $n_2$  can be found by examining the integers that were compared with  $n_1$ . Since  $n_1$  is compared with at most  $\lceil \log n \rceil$  integers (why?), we can use the result of the previous problem to conclude that  $n_2$  can be found by first determining  $n_1$  using n-1 comparisons, and then using the same algorithm on the elements that were compared with  $n_1$  to find  $n_2$ . This requires an additional  $\lceil \log n \rceil 1$  comparisions. This gives a total of  $n + \lceil \log n \rceil 2$  comparisons.
- 4. Pair up the integers and compare each pair. Place the greater integers in set G, and the lesser integers in set L. Now find the greatest element of G, and the least element of L.
- 5. Not true for groups of 3, since, in the worst-case, the new recurrence is  $T(n) = T(\lceil n/3 \rceil) + T(2n/3+6) + O(n)$  which yields log-linear growth in the worst case. This can be verified using the substitution method.
- 6. Use the Find-Statistic algorithm to determine the median M of the array, and use M as the pivot in the partitioning step. This ensures a Quicksort running time of T(n) = 2T(n/2) + O(n), since both subarrays are now guaranteed to have size n/2.
- 7. The 3rd quantiles occur at index values  $\lfloor n/3 \rfloor$  and  $\lfloor 2n/3 \rfloor$  (of the sorted array). This corresponds with k=6 and k=12. Associated with these indices are elements 5 and 8, respectively.
- 8. If we modify Find-Statistic to simultaneously find each of the quantiles (there are q-1 of them), then, since the quantiles are spread across the entire array, then, after the partitioning step, we will need to make recursive calls on both  $a_{\text{left}}$  and  $a_{\text{right}}$  (we may assume that we are using the exact median for the pivot during the partition step since the median can be found in linear time). The recurrence is thus T(n) = 2T(n/2) + O(n). Note however, that once the array sizes become sufficiently small during the recursion, there can be at most one quantile inside each array. Indeed, the quantiles are a guaranteed distance of n/q apart from each other. Moreover, the array sizes are being halved at each level of recursion, it will take a depth of  $\log q$  (verify!) before the array sizes are sufficiently small to only possess at most one quantile. When this happens, the normal Find-Statistic algorithm may be used, since now only a single k value is being sought. The running time is thus  $O(n \log q)$  for computational steps applied down to depth  $\log q$  of the recursion tree. The remainder of the tree consists of q problems of size n/q, and each of these problems can be solved in linear time using the original Find-Statistic algorithm. This yields an additional qO(n/q) = O(n) running time. Therefore the total running time is  $O(n \log q)$ .

9. We have

$$C_{12} = \hat{c}_{12} = \hat{a}_{11}\hat{b}_{12} + \hat{a}_{12}\hat{b}_{22} = A_{11}B_{12} + A_{12}B_{22} =$$

$$\begin{pmatrix} -2 & -4 \\ 4 & -2 \end{pmatrix} \begin{pmatrix} -1 & 2 \\ 4 & -1 \end{pmatrix} + \begin{pmatrix} 1 & 0 \\ -3 & 1 \end{pmatrix} \begin{pmatrix} -2 & -1 \\ -1 & 4 \end{pmatrix} =$$

$$\begin{pmatrix} -14 & 0 \\ -12 & 10 \end{pmatrix} + \begin{pmatrix} -2 & -1 \\ 5 & 7 \end{pmatrix} = \begin{pmatrix} -16 & -1 \\ -7 & 17 \end{pmatrix},$$

$$C_{21} = \hat{c}_{21} = \hat{a}_{21}\hat{b}_{11} + \hat{a}_{22}\hat{b}_{21} = A_{21}B_{11} + A_{22}B_{21} =$$

$$\begin{pmatrix} 1 & 0 \\ -3 & 2 \end{pmatrix} \begin{pmatrix} -1 & 4 \\ 3 & -3 \end{pmatrix} + \begin{pmatrix} -4 & -2 \\ 1 & -4 \end{pmatrix} \begin{pmatrix} -1 & 2 \\ -2 & -2 \end{pmatrix} =$$

$$\begin{pmatrix} -1 & 4 \\ 9 & -18 \end{pmatrix} + \begin{pmatrix} 8 & -4 \\ 16 & 10 \end{pmatrix} = \begin{pmatrix} 7 & 0 \\ 16 & -8 \end{pmatrix},$$

and

$$C_{22} = \hat{c}_{22} = \hat{a}_{21}\hat{b}_{12} + \hat{a}_{22}\hat{b}_{22} = A_{21}B_{12} + A_{22}B_{22} = \begin{pmatrix} 1 & 0 \\ -3 & 2 \end{pmatrix} \begin{pmatrix} -1 & 2 \\ 4 & -1 \end{pmatrix} + \begin{pmatrix} -4 & -2 \\ 1 & -4 \end{pmatrix} \begin{pmatrix} -2 & -1 \\ -1 & 4 \end{pmatrix} = \begin{pmatrix} -1 & 2 \\ 11 & -8 \end{pmatrix} + \begin{pmatrix} 10 & -4 \\ 2 & -17 \end{pmatrix} = \begin{pmatrix} 9 & -2 \\ 13 & -25 \end{pmatrix}.$$

Verify by direct multiplication of A with B that these are the quadrants of C = AB.

10. Consider the case where entry (i, j) lies in the upper right qudrant of C. Then we have

$$c_{ij} = \sum_{k=1}^{n} a_{ik} b_{kj}.$$

We must show that  $c_{ij}$  is equal to entry (i, j - n/2) of  $\hat{c}_{12}$ , where  $\hat{c}_{12}$  is the  $\frac{n}{2} \times \frac{n}{2}$  matrix that is entry (1, 2) of  $\hat{C}$ . To simplify the indexing notation, let

$$\hat{A} = \begin{pmatrix} p & q \\ r & s \end{pmatrix}$$
 and  $\hat{B} = \begin{pmatrix} t & u \\ v & w \end{pmatrix}$ 

be the respective quadrant matrices of A and B. Then matrices p through w are all  $\frac{n}{2} \times \frac{n}{2}$  matrices. Now,

$$\hat{c}_{12} = A_{11}B_{12} + A_{12}B_{22} = pu + qw$$

is the sum of two matrix products. Thus, the (i, j - n/2) entry of  $\hat{c}_{12}$  is equal to

$$\sum_{k=1}^{n/2} p_{ik} u_{k(j-n/2)} + \sum_{k=1}^{n/2} q_{ik} w_{k(j-n/2)} =$$

$$\sum_{k=1}^{n/2} a_{ik} b_{kj} + \sum_{k=1}^{n/2} a_{i(k+n/2)} b_{(k+n/2)j} =$$

$$\sum_{k=1}^{n/2} a_{ik} b_{kj} + \sum_{k=n/2+1}^{n} a_{ik} b_{kj} =$$

$$\sum_{k=1}^{n} a_{ik} b_{kj} = c_{ij},$$

and the proof is complete. The proof is similar for the cases when (i, j) is in either the lower left or lower right quadrant.

- 11. Padding the matrices with rows and columns of zeros to get a power of 2 number of rows will at most double the number of rows/columns of the matrix. But if  $T(n) = cn^k$ , then  $T(2n) = c(2n)^k = 2^k cn^k$ , and so the running time is still  $\Theta(n^k)$ .
- 12. We need the largest k for which  $T(n) = kT(n/3) + O(n^2)$  yields a better running time than  $T(n) = 7T(n/2) + O(n^2)$ . Thus we need  $\log_3 k < \log 7$ , or  $k = \lfloor 3^{\log 7} \rfloor$ .
- 13.  $\log_{68}(132, 464) \approx 2.795$ . Also,  $\log_{70}(143, 640) \approx 2.795$ , so they are approximately the same in terms of running time. They are slightly better than Strassen's algorithm, since  $\log 7 \approx 2.8$ .
- 14. We can think of the first matrix as a "column" of  $n \times n$  matrices  $A_1 \cdots A_k$ , where the second matrix as a "row" of  $n \times n$  matrices  $B_1 \cdots B_k$ . The product thus consists of  $k^2 \ n \times n$  blocks  $C_{ij}$ , where  $C_{ij} = A_i B_j$ . Thus, the product can be found via  $k^2$  matrix multiplications, each of size  $n \times n$ . Using Strassen's algorithm yields a running time of  $\Theta(k^2 n^{\log 7})$ .
- 15. ad,bc,(a+b)(c-d)
- 16. Use Find-Statistic to find the median m of a in linear time. Then create the array b, where b[i] = |a[i] m|. Then in linear time find the k th least element e of b (along with the subarray of elements of b that are all less than or equal to e). Translate these elements back to elements of a.
- 17. For the base case, if n=1, then  $a \cup b$  has two elements, each of which is a median. Now suppose n>1 is odd. Let  $m_a$  be the median of a, and  $m_b$  the median of b (both can be found in constant time since both arrays are sorted). If  $m_a=m_b$ , then  $m_a=m_b$  are the two desired medians. of  $a \cup b$ . Otherwise, assume WLOG (without loss of generality) that  $m_a < m_b$ . If m is a median of  $a \cup b$ , then we must have  $m_a \leq m \leq m_b$ . Otherwise, suppose, e.g., that  $m < m_a$ . Then there would be more elements of  $a \cup b$  that are to the right of m (why?). Similarly, it is not possible for  $m > m_b$ . Hence, the elements  $a_L$  of a to the left of  $m_a$  must be less than or equal to m. Similarly, the elements  $b_R$  of b to the right of  $m_b$  must be greater than or equal to m. Thus, if we remove  $a_L$  from a and  $b_R$  from b, we obtain two odd-lenthed arrays that are now half the size, yet that still have the same medians as the previous arrays. Repeat the process until the base case is reached. Running time is  $O(\log n)$ , since it satisfies the recurrence T(n) = T(n/2) + 1.
